§1 INFTY-QUEENS INTRO 1

1. Intro. What's the lexicographically smallest solution to the ∞ -queens problem? I mean, consider the sequence q_0, q_1, \ldots , where q_n is the least nonnegative integer not in the sets $\{q_k \mid 0 \leq k < n\}$, $\{q_k + k - n \mid 0 \leq k < n\}$, $\{q_k - k + n \mid 0 \leq k < n\}$.

Inspired by Eq. 7.2.2–(6), I maintain bit vectors a, b, c to record the occurrences of q_k , $q_k + k$, and $q_k - k$, for previously calculated values. Thus, for example, we'll have $c_r = 1$ if and only if $q_k - k = r$ for some k < n, when I'm calculating q_n . The value of q_n will be the smallest k > 0 such that $a_k = 0$ and $b_{k+n} = 0$ and $c_{k-n} = 0$.

It turns out (as conjectured by Neil Sloane in 2016, and proved by him and Jeffrey Shallit shortly thereafter) that this sequence has lots of beautiful structure, which greatly facilitates the computation. Let ϕ be the golden ratio. Then the subscripts of a will range from 0 to approximately ϕn ; the subscripts of b will range from 0 to approximately $\phi^2 n$; and the subscripts of b will range from approximately b0 to approximately b1. In particular, since b2 has b3 bits equal to 1, and b1 had b2 had b3 had b4 had b5 had b6 equal to 1. Furthermore, b6 will begin with a string of 1s, whose length is approximately b1. Therefore we only need to look at a bounded number of bits when we're computing b2.

Nice, huh?

This implementation uses one byte per bit. Of course I could make n eight times larger by packing the bits.

Another feature is an exact computation of the discrepancies between q_n and ϕn or $\phi^{-1}n$. For example, this program "knows" that $q_{F_{40}} = F_{41} = \phi F_{40} + \phi^{-40}$.

```
/* approximation when we allocate memory */
#define slack 10

  o, b[q + n] = 1; got_q:
This code is used in section 1.
```

5. I had special fun writing the next part of this program, which expresses the value of $n\phi$ as an integer plus $\sum_{k\geq 1} x_k \phi^{-k}$, with $x_k x_{k+1} = 0$ for all k. For example, $9\phi = 14 + \phi^{-2} + \phi^{-4} + \phi^{-7}$. We maintain the integer part in *nphiint*, and the fractional part in *nphifrac*, where the latter is the *binary* integer $(\dots x_3 x_2 x_1)_2$.

This fractional part has a nice connection with the negaFibonacci number system, which is described in equation 7.1.3–(147) of The Art of Computer Programming. For example, $9 = F_{-7} + F_{-4} + F_{-2}$ is the negaFibonacci representation of 9; hence we have $9\phi = (F_6 - F_4 - F_2)\phi = F_7 - F_5 - F_3 - ((-\phi)^{-7} + (-\phi)^{-4} + (-\phi)^{-2}) = 14 + \phi^{-7} + \phi^{-4} + \phi^{-2}$.

Furthermore, equation 7.1.3–(149) shows a nice way to go from the negaFibonacci representation of n to its successor. And exercise 7.1.3–45 shows that it's surprisingly easy to compare the fractional parts, even if they are ordered lexicographically from right to left instead of from left to right(!).
